Abstract

TITLE: MYCOPLASMA ARGININI INCREASES ACTIVATION, ENERGETIC DERRGULATION, AND TUMOR PROGRESSION OF VM-M3 METASTATIC MACROPHAGE CELLS.

AUTHOR: ROBERTO ETTORE FLORES

Thesis Advisor: Thomas N. Seyfried, Ph.D.

Mycoplasmas are the smallest, self-replicating free-living prokaryotes, and have been associated with carcinogenesis. Mycoplasmas can be detected in a high percentage of a wide variety of primary human cancers. Some mycoplasma species such as M. fermentans and M. hyorhinis can transform normal murine and human cell lines into tumorigenic cells. Mycoplasma infection can activate oncogenes as well as inactivate tumor suppressor genes. These observations suggest that mycoplasmas can be both carcinogenic and or onco-modulatory. I found that the metastatic macrophage VM-M3 cell line (referred to as M3+) was infected with mycoplasmas. Mycoplasmal 16S rDNA sequencing showed M3+ cells were infected by the mycoplasma species M. arginini. Antibiotic was used to eradicate M. arginini from M3+ cells (referred to as M3- cells). The energetics of the infected M3+ cells and the non-infected M3- cells was studied by measuring respiration (oxygen consumption) and fermentation (lactate production). Respiration was enhanced and fermentation was reduced in the M3- cells compared to the M3+ cells. Glucose enhanced the fermentation and reduced the respiration of both the M3+ and the M3- cells. The M3+ cells produced higher quantities of metabolites indicative of
immunological activation (itaconic acid, succinate, and citrulline) compared to M3-cells. In addition, in-vitro proliferation was higher in the M3+ cells than in the M3-cells at high cell densities. Primary subcutaneous tumor growth and metastasis was less in mice inoculated with the M3- cells than with the M3+ cells. The survival of a VM mouse was longer when inoculated with the M3- cells compared to the M3+ cells. Altogether these data indicates that M. arginini is an onco-modulator associated with activation, deregulated energetics and enhanced tumor progression of VM-M3 metastatic macrophage cells.

Introduction

Mycoplasmas of the Mollicutes class are considered the smallest self-replicating free-living prokaryotes (1). Mycoplasma 16S rRNA sequencing data used as a phylogenetic measure suggests that mycoplasmas originated from walled gram-positive eubacteria by degenerative evolution roughly 600 million years ago (2). Unlike their walled ancestors, the Mollicutes (soft skin) class lacks a cell wall and thus is resistant to common bacterial cell wall targeted antibiotics such as penicillin. Mycoplasmas range in size from 0.3µm to 0.8µm, which in turn reflects their small genome sizes. *M. genitalium* has the smallest genome (580 kb) of any organism that can be grown in pure culture and *M. hyorhinis* has the largest genome of the mycoplasmas (820 kb) (3) (2) (4). With limited coding capacity, the mycoplasma genus has stringent nutritional requirements for fatty acids, sterols, some amino acids, nucleic acids, and various vitamins/cofactors (4) (5). Dependence on metabolic precursors for life leads to the need of extremely complex media in order to cultivate and therefore study mycoplasmas. However, high mycoplasma infection rates show that mycoplasmas propagate well within or attached to mammalian cells in-vitro (6) (1).

Mycoplasma infection of cultured mammalian cells can falsify many metabolic and non-metabolic cellular assays including oxygen consumption assays (7), nitric oxide synthase activity (8), MTT viability assays (9), and mitochondrial protein synthesis determination (mycoplasma co-purified with the mitochondrial fraction) (10). In agreement, *M. hominis* infection of HeLa cells significantly altered genetic expression
profiles of 1972 genes (11). Another study found approximately 200 significant expression profile alterations in infected MCF7 cells and 70 of those genes were involved in metabolism (12). In Mycoplasma pneumoniae-infected individuals, tracheal cell explants were shown to have a decrease in ATP from respiration, possibly due to lower dehydrogenase activities of the cells (10). Similarly, M. hyorhinis is also capable of reducing the respiration system in heavily contaminated human skin fibroblast cells (13). Thus, mycoplasmas have a high potential for modulating host metabolism.

Regarding energy catabolism, mycoplasmas can be classified as fermentative or non-fermentative (14). Fermentative mycoplasmas are able to gain energy by substrate-level phosphorylation of ADP by glycolysis, specifically by the Embden-Meyerhof-Parnas (EMP) Pathway (14). Fermentation produces acid and occurs not to specifically make energy, but rather to oxidize NADH to allow glycolysis to continue to make energy (NAD+ is required for the 6th step of glycolysis) (15). Therefore, fermentative mycoplasmas are acidifiers and thus reducers of their environment. Some fermentative mycoplasmas such as M. gallisepticum have the ability to carry out a non-fermentative catabolism (16) (17) but viability and growth during a non-fermentative catabolism are unclear. However in the presence of glucose, fermentative mycoplasmas produce a net waste of acid. In contrast, non-fermentative mycoplasmas do not produce a net waste of acid or alcohol, which indicates that their energy catabolism is mainly oxidative. In part, the oxidative catabolism of the non-fermentative mycoplasmas is perhaps due to the lack of
phosphofructokinase and aldolase activity of the EMP pathway in these organisms (14). Thus, respiration (oxidation) rather than fermentation (reduction) characterizes the non-fermentative mycoplasmas.

Even though non-fermentative species of mycoplasma seem unable to ferment glucose, they possibly generate energy anaerobically through the arginine dihydrolase pathway (18). However, the aerobic or anaerobic contribution of the arginine dihydrolase pathway to overall energy generation in any one species is unclear. Some non-fermentative mycoplasma species require arginine for growth, while other species can grow without arginine. For example, only one of three strains of \textit{M. arginini} was found to require arginine for growth (19). \textit{M. arginini} was named as so simply because the author discovered that arginine boosted growth, rather than glucose or urea. (20). Whether arginine is utilized by non-fermentative mycoplasmas more for catabolic or anabolic needs is unclear (21) (19) (22). Since \textit{M. arginini} contains a flavin-terminated respiratory chain it is likely that \textit{M. arginini} uses both respiration and the arginine dihydrolase pathway for energy production according to oxygen levels and metabolic fuel supply set by the environment (19).

In hypoxic conditions that may not allow for sufficient energy generation from respiration, arginine-utilizing mycoplasma would most likely generate energy through the anaerobic arginine dihydrolase system, just as the fermentative mycoplasmas would generate energy through anaerobic lactate fermentation.

Even though the interaction between host and mycoplasma is typically commensal,
mycoplasmas are well known for their parasitic nature (23), partly due to their fastidious metabolic needs (4) and partly due to their ability to promote chronic inflammation (24). Various strains of mycoplasmas are capable of causing disease as well as implicated as co-factors in dozens of others, but their virulent capabilities and potential are just beginning to unfold (25) (26) (27) (23) (24). Irrespective of the role mycoplasmas play in disease as benign colonist, co-contributors, or even the cause, they have a robust ability to modulate inflammation, metabolism, and cancer.

A search for the link between mycoplasmas and cancer began after some mycoplasma species were shown to be sufficient in causing non-tumorigenic cells to transform into tumorigenic cells (28) (29). In addition to the classic hallmarks of cancer, an emerging hallmark is deregulated energetics (30). As detailed above, mycoplasmas seem sufficient in deregulating cellular energetics. Also, mycoplasmas have been shown to induce cells to evade apoptosis (31) (32), sustain proliferation (24) (5), enable replicative immortality (33), and activate invasion and metastasis (34) (35), which are all four classic hallmarks of cancer (30). Alongside the deregulating of cellular energetics, the other emerging hallmark of cancer cells is the ability to avoid immune destruction. Recently, mycoplasma infected tumor cells were found to release exosomes that activate inhibitory B-cells, which in turn inhibit T cells cytotoxic to cancer cells (36). Interestingly, mycoplasmas also cause genomic instability (37) (38) and inflammation (39) (40), both major hallmark-enabling characteristics of neoplasia. In addition, mycoplasma infection is strongly
associated with onco-genetic alterations. During transformation of non-tumorigenic C3H mouse embryo cells into tumorigenic cells, *M. fermentans* and *M. penetrans* have been shown to cause constitutive H-ras and c-myc expression (41). Moreover, *M. arginini* infection has been shown to cooperate with oncogenic Ras, activate NF-kB, and suppress p53 (32). All mycoplasma species tested by these authors suppressed p53, but *M. arginini* showed the greatest ability to suppress p53. In addition to mycoplasma infection being strongly linked to the hallmarks and characteristics of cancer, their presence in a variety of human primary tumor samples strengthens the possibility of a causative or at least a modulatory role in human carcinogenesis (28) (42) (43) (44) (45). The ability of mycoplasmas to cause chronic inflammation and activate NF-kB further strengthens the link between mycoplasma, inflammation and cancer.

Although some immune cells can help eradicate tumor cells, inflammation created by tumor-associated immune cells ultimately balances out towards that of tumor promotion rather than of regression (46). In agreement with the surprising and counterintuitive findings that immune cells ultimately promote tumor progression, tumor-associated immune cells have been found to enable some of the hallmarks of cancer (30). Many types of immune cells are able to promote tumor progression, including T lymphocytes, B lymphocytes, and macrophage subtypes (47) (48). Typically, type M2 macrophages are thought to stimulate cancer progression while type M1 macrophages have been shown to be important for tumor regression (48). However, Egeblad et al. suggest that tumor-associated macrophages (TAM) may be a
continuum of various M1 and M2 subtypes rather than rigidly being classified as solely M1 or M2 (49). Regardless of the exact type of macrophage, the transcription factor Hypoxia Inducible Factor 1-alpha (HIF-1α) has been described to be a master regulator for tumor promoting TAM (50). The HIF-1α expression of TAM links tumor-promoting inflammation and deregulated cellular energetics, i.e. a hallmark-enabling characteristic of cancer with an emerging hallmark of cancer, respectively (51). Tumor-promoting inflammation is referred to as “smoldering” because of its chronic and low-grade nature (52). Interestingly, mycoplasma-induced inflammation seems to recapitulate tumor-promoting inflammation as both are NF-κB-driven, chronic and low-grade in nature (53). The link between infection, chronic inflammation, and cancer has been noted (54).

My study investigates the metabolic and tumorigenic consequences of *M. arginini* infection in metastatic murine macrophage tumor cells (VM-M3 cells). The VM-M3 tumor arose spontaneously in the cerebrum of a male adult VM/Dk mouse. The VM-M3 cells (M3) are more specifically characterized as microglia since they express morphological, behavior, biochemical, and genetic properties of macrophages (55). When inoculated in the syngeneic VM mouse host, M3 cells recapitulate all major biological processes of metastasis to include local invasion, intravasation, immune system survival, extravasation and secondary tumor formation involving liver, kidney, spleen, lung and brain (55). Inoculation of M3 directly into the brain seems to biologically mimic the characteristics of glioblastoma seen in the human (56). In the present study the M3 cells were diagnosed with an *M. arginini* infection,
however the origin or date of the infection is unclear. After eradication of *M. arginini* from M3 cells, the energy catabolism and other metabolic pathways between the infected (M3+) and non-infected (M3-) cells were assessed. In addition, the differential effects of the M3+ and M3- cells inoculated in-vivo were examined. My data suggests that *M. arginini* is capable of increasing tumor progression possibly through tumor-promoting inflammation and deregulation of cellular energetics. Since mycoplasmas can be detected in a high percentage of a wide variety of primary human cancers (28) (42) (43) (44) (45), therapies targeting mycoplasma-infected tumors may benefit cancer patient survival.
Materials and Methods

Cell lines and culture conditions
The VM-M3+ cell line was established from flank-grown VM cerebral tumors as previously described (55). VM-M3 (M3) cells were grown in Dulbecco’s modified Eagle medium (DMEM, Sigma, St. Louis, MO) with high glucose (25 mM) supplemented with 10% fetal bovine serum (FBS, Sigma) and 50 lg/ml penicillin-streptomycin (Sigma). M3 cells were cultured in a CO2 incubator with a humidified atmosphere containing 95% air and 5% CO2 at 37C. The M3 cells were passaged approximately one time per week or when 80% confluency was reached. The M3II cells (clone II) were treated exactly as the M3 cells.

Eradication and Identification of Mycoplasma
VM-M3 cells were eradicated by adding MycoZap (Lonza) to the culture media for one week, with the starting point being right after cells plated down to the culture plastic at low density (100,000 cells/100mm dish). In a separate incubator a control dish of VM-M3 cells with no mycoplasmal targeted antibiotics was treated and passaged in conjunction with the MycoZap treated dish at all times. The media was changed every 48 hours and no change in growth or cell death was noted. A subsequent treatment of ciprofloxacin (10ug/mL) was used for one week as a prophylactic strategy exactly as described for MycoZap above. After one week of ciprofloxacin prophylactic treatment the VM-M3 cells were grown for an additional week only with the usual Penicillin/streptomycin antibiotics, which were not
removed during MycoZap/Ciprofloxacin treatments. Treated VM-M3 cells and untreated VM-M3 cells were subjected to a MycoAlert Detection Assay and e-myco Plus PCR detection (Bulldog Bio)(Figure 1) to verify eradication of infection. Identification of *M. arginini* infection was done by excision and sequencing of the positive 260 bp 16S rDNA band in an e-Mycoplasmal 16S rDNA sequence (query) was BLAST searched against the GenBank database and the best match (subject) or top score was *Mycoplasma arginini*.

**Oxygen consumption and Extracellular Acification Rate, and Lactate Measurements**

Oxygen consumption rate and Extracellular acidification rate (ECAR) was taken with a Seahorse XF96 Extracellular Flux Analyzer. M3+ or M3- cells were seeded at 30,000 cells per XF96 plate well and allowed to incubate for 12 hours in DMEM high glucose with 10% FBS. The media was then changed to complete media with or without 100 nM Antimycin A (complete media: DMEM with 2 mM glutamine, 10mM glucose, and 0.5 mg/mL Albumax I. No FBS and no bicarbonate were included in the media as recommended by Seahorse for ECAR measurements. Phenol red was not included since visual pH monitoring was unnecessary. The Crabtree effect was circumvented by simply not including glucose in complete media). Two hours later the media was changed again to complete media and the plate was quickly inserted into the XF96 analyzer. The XF96 analyzer was programmed to take 7 minute measurements with a 1-minute mix and a 1-minute wait period before a subsequent
7 minutes measurement was taken. The total measurement time was 2 hours and the average O2 consumption was calculated. O2 consumption rate and ECAR were steady throughout the 2 hour time period.

Lactate production rate was assessed by collection of the media of each XF analyzer 96-well with a subsequent Eton Bioscience’s L-lactate assay I kit. Taking the millimoles of lactate and multiplying by the total microliters in each well determined the total millimoles of lactate. The total O2 consumption rate, ECAR value, and lactate production rate was corrected to the milligram protein in each XF96-plate well. Thus, oxygen consumption, ECAR, enzymatic lactate, and protein were all measured from the same well.

To assess oxygen consumption in the M3II clone a Presens Sensor Dish Reader (SDR) in an airtight Coy Laboratory Chamber was utilized (termed the SDR plus). The percentage of gas in the chamber was set at 20% oxygen, 5% CO2, and 75% N2. 125,000 cells/ml were seeded in a 24-well PreSens OxoDish® plates in 500 ul of DMEM high glucose plus 10% FBS and allowed to settle for 3 hours before addition of new DMEM high glucose 10% FBS at which t=0. Cell # was assessed with a Millipore Scepter. The cell number per well was the same for BV-2, M3LM and M3 at time of initial seeding. While the cells incubated the SDR Plus assessed % O2 at the bottom of the dish every 3 minutes for 48 hours. Since there is 20% O2 in the SDR plus environment (translating to > 20 % in the media), the % O2 recorded in wells
with cells is subtracted from no cell containing wells to yield the %O2 consumed at 48 hours.

**Western Blot**

For western blot analysis, VM-M3+ and VM-M3– cells were lysed in ice-cold RIPA lysis buffer containing 1x TBS, 1% Nonidet P-40, 0.5% sodium deoxycholate, 0.1% SDS, and 0.004% sodium azide supplemented with PMSF, protease inhibitor cocktail, and sodium orthovandate (Santa Cruz Biotechnology, Inc., Santa Cruz, CA, USA). Lysis was performed on ice for 30 minutes. Protein was then obtained by centrifugation at 12,000 x g for 20 minutes at 4°C. The amount of protein in the sample was determined using the Pierce BCA Protein Assay (Thermo Scientific). Samples containing 20 µg of protein were boiled in NuPAGE LDS Sample Buffer and separated on NuPAGE 4%–12% bis-Tris gels (Invitrogen). The proteins were electrophoretically transferred to a Low-Flourescence PVDF Transfer Membrane at 20 V overnight at 4°C. The membrane was blocked in Odyssey Blocking Buffer for 1 hour and then probed with antibodies against Complex IV, subunit IV (1:2,000) (clone 20E8; Molecular Probes, Eugene, Oregon, USA), LDHA (1:1,000) (#2012S; Cell Signaling Technology, Danvers, MA, USA), and β-actin (1:7,500) (Clone AC-74; Sigma-Aldrich) overnight at 4°C. The blots were then incubated with the corresponding Odyssey secondary antibodies Goat anti-Rabbit IRDye 800CW (1:20,000) (827-08365) and Donkey anti-Mouse IRDye 800CW (1:20,000) (926-32212) (LI-COR Biosciences). The proteins were visualized using the Odyssey Classic imaging system (LI-COR Biosciences). The intensity of each band was
determined using Image Studio Lite software (LI-COR Biosciences). Complex IV, subunit IV and LDHA expression were normalized to the intensity of the β-actin band. Statistical analysis was performed using IBM SPSS Statistics software. A two-tailed t-test was performed and the significance values were determined for the ratios of both Complex IV, subunit IV and LDHA to β-actin for both VM-M3 + and VM-M3 – cells.

**Protein Quantification**

For protein determination of Seahorse XF96 assay plates, 40 µl of RIPA lysis buffer (described above in detail for Western Blot) was added to each aspirated well and mixed by pipetting up and down 25 times. The plates were then incubated on an orbital shaker for 15 minutes at 200 rpms. The mixing step was repeated, the plate was incubated on ice, and the protein was subsequently quantified using 25 µl in the Pierce BCA Protein Assay (ThermoScientific) according to the manufacture’s protocol. Protein quantification for proliferation assays was done in the same manner.

**Proliferation and Luminescence Output Assays**

ATP determination over 2 days in black walled 96-well cell culture treated plates was used to assess in-vitro proliferation of M3+ and M3— cells initially seeded at 15,000 cells/well. The cooled CCD camera on the Xenogen IVIS Lumina system (Xenogen, Hopkington, MA) was used to record the photons / second (over 10 seconds) emitting from a luminescence reaction after performing a CellTiter-GLO
Luminescent ATP assay (Promega, Madison, Wisconsin) according to the manufacture's protocol. In addition, in-vitro proliferation over 5 days of M3+ and M3- cells seeded at 5,000 cell/well in 96-well cell culture plates was assessed using a Pierce BCA protein assay. At 1, 3, and 5 days the protein was collected from each well as described in Protein Quantification section above. For the luminescent output assay the same procedure as the ATP proliferation assay was used, however with the following changes: rather than the CellTiter-GLO assay, the M3 cell endogenous firefly luciferase vector and added D-luciferin (Promega) was used to initiate the bio-luminescence reaction. Also, cells were not allowed to proliferate as the bio-luminescence was gauged at 4 hours after seeding M3+ or M3- cells (M3 cells attach to the bottom of the dish in ~ 2 hours). During the luminescence output assay progressive microgram amounts of luciferin were added to a 120ul of growth media with 30,000 cells / well in a black walled 96-well cell culture treated plate.

**Mice**

Mice of the VM/Dk (VM) strain were obtained as gifts from G. Carlson (McLaughlin Research Institute, Great Falls, Montana) and from H. Fraser (University of Edinburgh, Scotland). All VM mice used in this study were housed and bred in the Boston College Animal Care Facility using husbandry conditions as described previously (57). All animal procedures were in strict accordance with the NIH Guide for the Care and Use of Laboratory Animals and were approved by the Institutional Animal Care Committee.
**Subcutaneous inoculation of M3+ and M3- cells**

The M3+ and M3- cell lines were grown to confluency in 245 mm cell culture dishes, scraped in PBS containing 25 mM glucose and 4 mM glutamine (PBS+), washed and then re-suspended in PBS+. Subsequently, 1.5 million M3+ or M3- cells were subcutaneously injected in a 0.5 mL volume of PBS into the back or flank region of VM/Dk mice.

**Assessment of tumor progression in VM mice**

Morbidity of VM/Dk mice was used as an endpoint to in-vivo experiments I, II, and the metastasis/survival study using M3II clones. However, in experiments I and II M3- inoculated mice were not morbid but were sacrificed in order to compare tumor progression to M3+ inoculated mice. For experiments I and II, primary tumors were excised, frozen, and weighed. In the metastasis/survival study using M3II clones, mice were imaged with the Xenogen IVIS Lumina system (Xenogen, Hopkington, MA) to record the bioluminescent photon signal from the VM-M3/Fluc tumors. For in vivo whole body imaging in the metastasis / survival study, mice received an i.p. injection of D-luciferin (50 mg/kg, Xenogen) and Avertin (0.1 ml/10 g) and mice were imaged for 1 minute. For ex vivo imaging during in-vivo experiment II, the brain was excised and placed in a Petri dish with 300 mg/ml D-luciferin in PBS, and imaged for 10 seconds.

**Extraction of Metabolites and Capillary Electrophoresis Time-of-Flight Mass Spectrometry**
M3+ and M3- cells were incubated in complete media (DMEM amino acid mixture, 10 mM glucose, 2 mM glutamine, and Invitrogen’s albumax I; no bicarbonate, phenol red, or FBS added) for 6 hours in an incubator with 100% air at 37°C (0% CO2). Subsequently after washing the cells twice in a 5% (w/v) mannitol water solution the metabolites were extracted with methanol and an internal standard water solution. The samples were kept on ice, ultra-filtered in custom Human Metabolome Technology centrifugal tubes at 4°C, and the flow through was vacuum dried for ~2 hours. Metabolome analysis was performed by HMT using Capillary Electrophoresis Time-of-Flight Mass Spectrometry in two modes for cationic and anionic metabolites. The analysis detected 173 metabolites (89 metabolites in cation mode and 84 metabolites in anion mode) on the basis of HMT’s standard library.
Results

**Discovery and Eradication of Mycoplasma Infection in VM-M3 cells**

Mycoplasma infection in VM-M3 cells was first diagnosed enzymatically with a MycoAlert® Mycoplasma Detection Kit (data not shown). In light of a positive infection, the VM-M3 cells are referred to as VM-M3+ (abbreviated M3+). To verify the enzymatic detection of mycoplasma, PCR amplification of a 260 bp region of mycoplasmal 16S rDNA gene was performed using primers able to identify 182 species of mycoplasma. Positive amplification indicative of a positive infection was seen by the presence of a 260 bp band in the +control and M3+ lane (Figure 1A). After eradication of mycoplasma infection with mycoplasma-targeted antibiotics, no band at 260 bp could be detected indicating a successful eradication (M3- lane). After eradication and in light of a negative infection, this cell line was named M3-. Three weeks after eradication, the M3- cells remained free of mycoplasma infection (Figure 1B).

**Mycoplasma arginini infection of VM-M3 cells**

The 260 bp region of amplified mycoplasmal 16S rDNA gene from the infected M3+ cells was excised from the gel, purified, and sequenced. BLAST was used to align the mycoplasmal 16S rDNA (query) to subject sequences in GenBank. The top score identified the query sequence as derived from *Mycoplasma arginini* (Figure 2A). The 16S sequence belonging to *Mycoplasma hominis*, a phylogenetically close
relative to *M. arginini*, (2) received a lower score in light of the mismatch/gap alterations (Figure 2B).

**Influence of *M. arginini* on respiration in VM-M3 cells**

According to bioenergetics principles mammalian cells are able to respire amino acids and fatty acids for energy (15) (Figure 3). In order to compare the respiratory systems in M3+ and M3- cells, a Seahorse XF96 analyzer was utilized (Figure 4). In the presence of amino acids, fatty acids, and glucose (complete media) the eradicated M3- cells show an elevated respiration rate compared to the infected M3+ cells (Figure 5A). Oxygen consumption rate dropped by 84% and 85% in M3+ and M3- cells, respectively, following addition of the respiratory inhibitor Antimycin A (AntA). Thus, approximately 15% of oxygen consumption in both cell lines is unassociated with respiration in complete media. *M. arginini* eradication in M3- cells elevated respiration by 29%, after subtracting the AntA insensitive oxygen consumption.

Extracellular acidification rate (ECAR) is often used to estimate lactate fermentation. However, ECAR is an indirect measure of lactate fermentation as the protons expelled with lactate are measured rather than lactate. ECAR is higher in the M3- cells than in the M3+ cells and fails to elevate under AntA treatment in M3+ cells (Figure 5B). Direct enzymatic measurement of L-lactate is preferred as a more reliable measure of lactate fermentation rate as many factors can influence pH other than lactate efflux.
As an alternative to ECAR, an enzymatic assay was used to estimate lactate production (a measure of fermentation). Unlike the ECAR value, lactate production increased in M3+ when respiration was inhibited by AntA, as would be expected (Figure 5C). Lactate production was greater in M3- cells than in M3+ cells in the presence of AntA. No difference in lactate production was found between M3+ and M3- when lactate production was corrected to protein levels (Figure 5C). However, when lactate production was corrected to ATP levels and cell number, M3- cells made less lactate than M3+ cells (Figure 6). When compared to the M3+ cells, the reduced lactate production by M3- cells is in agreement with their higher respiration rate. The lower respiration and higher fermentation of M3- cells compared to M3+ cells is unable to be explained by differences in Cytochrome C Oxidase and LDHA protein levels (Figures 7A-D).

**Influence of M. arginini on the Crabtree effect in VM-M3 cells**

Cancer cells and other non-tumorigenic highly glycolytic cells experience a Crabtree effect, i.e. glucose-induced suppression of respiration (58) (59) (60). Suppression in respiration from a Crabtree effect can be measured by using media devoid of glucose, since respiration becomes un-suppressed (61). Both the M3+ and the M3- cells demonstrated a Crabtree effect when 10 mM glucose (+glc) was added to glucose-absent media (-glc) that consisted an amino acid mix, 2 mM glutamine, and albumin conjugated fatty acids (Figure 8A). The M3+ and M3- cells experienced a 21% and 30% Crabtree effect, respectively, when solving for the % Crabtree effect.
equation of Wenner (59) (Table 1 & Figure 8B). In other words, glucose addition suppressed the respiration of M3+ and M3- cells by 21% and 30%, respectively.

Respiration rate measured during the Crabtree is misleading because of variability in % Crabtree effect of difference cell lines. Uns suppressed-respiration (during Crabtree effect-circumvention) is a more accurate indication of a cell lines maximum respiratory rate. During the Crabtree effect the M3- cells have a 29% increase in respiration compared to M3+ cells. However, when the Crabtree effect is circumvented by glucose removal the M3- cells show a 37% increase in respiration over that of M3+ cells (Figure 8A). Regardless of the presence or absence of the Crabtree effect, M. arginini eradication results in a significant increase in respiration rate in VM-M3 cells.

**Influence of M. arginini on activation metabolites in VM-M3 cells**

Several activation-specific metabolic markers for macrophages are characterized and validated. Itaconic acid is a bactericidal product of activated macrophages (62) (63) (64). The production of itaconic acid dropped more than two-fold in the M3- cells compared to the M3+ cells (Figure 9). Another key metabolite recently found to be produced by activated macrophages is succinate, which is metabolized partly from GABA (the GABA shunt) (65). GABA and succinate was significantly reduced in M3- cells compared to M3+ cells (Figure 10). In addition to itaconic acid and succinate, another indicator of macrophage activation is Nitric Oxide (NO) made by Nitric Oxide Synthase (NOS) by metabolism of arginine to citrulline (66)(67).
Therefore, arginine metabolism to citrulline indicates NO production. In the infected M3+ cells arginine metabolism to citrulline was detected compared to barely detectible arginine to citrulline metabolism in the M3- cells (Figure 11).

**Influence of *M. arginini* on the in vitro proliferation of VM-M3 cells**

Elevated intra-cellular metabolites of the Pentose Phosphate Pathway (PPP) metabolites are indicative of enhanced cellular proliferation, as the PPP supplies metabolic precursors for DNA and RNA synthesis (68). Glucose is the precursor for the synthesis of Ribose-5-Phosphate (R5P), Ribulose-5-Phosphate (Ru5P), and Phosphoribosyl Pyrophosphate (PRPP). R5P, Ru5P, and PRPP provide the necessary ribose for de novo nucleic acid synthesis (69). The M3+ cells showed elevated intra-cellular levels of the PPP metabolites R5P, Ru5P, and PRPP compared to the M3- cells (Figure 12). Reduced intra-cellular PPP metabolite concentration was concomitant with a reduced proliferation rate at higher cell densities in the M3- cells compared to the M3+ cells (Figure 13). Therefore, eradication of *M. arginini* resulted in a lower in-vitro proliferation rate in M3 cells only at high cell densities.

**Influence of *M. arginini* on the in vivo tumor growth of VM-M3 cells**

The M3+ cells metastasize systemically following subcutaneous inoculation in the syngeneic VM/Dk mouse host. Approximately 1.5 million M3+ or M3- cells were inoculated subcutaneously in the back (experiment 1) or the flank (experiment 2) of the VM/Dk mice. Experiment 1 was terminated after 21 days and experiment 2 was terminated after 30 days when the mice with the M3+ cells became moribund
(reduced ambulation due to tumor burden). None of the mice inoculated with M3-cells became moribund. Wet weight was less for the tumors produced from the M3-cells than for the M3+ cells (Figure 14A & 14B).

**Influence of *M. arginini* on the in vivo metastasis of VM-M3 cells**

The M3+ cells are transduced with a firefly luciferase lentivirus vector under the control of the constitutive CMV promoter. By injecting luciferin into VM mice it is possible to monitor growth and movement of M3 cells in-vivo by detecting the emitting photons (Figure 15). Oxygen is a necessary substrate for the luciferase light-emission reaction. The M3+ cells consumed less oxygen than the M3- cells (Figures 5 and 8A). In addition, the M3+ cells produce less light than M3- cells from the luciferase reaction (Figure 16).

In experiment 2, metastasis to liver and brain was assessed. Metastatic nodules to liver and metastatic brain luminescence were qualitatively less in M3- inoculated mice compared to M3+ mice (Figure 17). Brain luminescence in M3- mice was reduced by a factor of 2.66 to account for the greater luminescence output of the M3- cells compared to the M3+ cells.

**Influence of *M. arginini* on oxygen consumption and tumor progression in a VM-M3 tumor variant clone**
Cells comprising tumors are genetically heterogeneous and therefore it is possible that two clonal cell lines created from the same tumor can exhibit different metabolotypes. In order to control for this phenomenon, a different clone of the VM-M3 tumor (M3 clone II) was isolated from a firefly luciferase transduced-monolayer of cells from a separately passaged VM-M3 tumor chunk that gave rise to the M3 cells (original clone). M3 clone II (M3II) also tested positive for mycoplasma infection (M3II+) via the enzymatic mycoalert (Lonza) assay and was eradicated (M3II-) with a 1 week treatment of MycoZap (Lonza). Using an SDR plus system to measure oxygen consumption, eradicated M3II- cells showed a marked elevation of respiration compared to the M3II+ cells (Figure 18A). When M3II+ and M3II- cells were inoculated in VM mice (1 mouse for each cell line) the eradicated M3II- cells showed reduced primary tumor growth, metastasis, and longer survival (Figure 18B). These results with a different clone of the VM-M3 tumor (M3II) are in agreement with studies done with the original clone (M3).
Discussion

*M. arginini*-infected M3 cells produce metabolites suggestive of activation.

*M. arginini* produces a low molecular weight protein termed Macrophage-Triggering Factor (MTF) that activates macrophages (70). Once activated, macrophages and microglia exert cytotoxic effects by releasing inflammatory mediators, such as arachidonic acid metabolites, interleukin-1 (IL-1), nitric oxide (NO), reactive oxygen species (ROS), and tumor necrosis factor-alpha (TNF-α) (71) (72). In fact, macrophages are potent secretory cells that release a plethora of mediators in response to activation (73). One of these activation markers was recently shown to be itaconic acid (62), which was corroborated in a subsequent independent study (63). Itaconic acid is a small metabolite that inhibits bacterial isocitrate lyase as well as glycolysis via the inhibition of phosphofructokinase (64) (74) (75). Therefore, itaconic acid could be both a bactericidal and an anti-glycolytic metabolite. The M3+ cells produce more than two-fold the amount of itaconic acid than M3- cells suggesting that M3+ cells have an elevated levels of activation compared to the M3- cells (Figure 8).

Another metabolite made by activated macrophage cells is succinate (65). In activated bone marrow derived macrophage cells (BMDM) succinate is made partly through the GABA shunt, which shunts GABA metabolized from glutamate towards succinate production. The LPS-induced succinate production of BMDM results in HIF-1α stabilization, elevated glycolysis, and subsequent IL-1β production. In
addition, BMDM activation results in a down-regulation of mitochondrial genes and up-regulation of glycolytic genes suggesting that activation of BMDM leads to lower respiration and a higher fermentation. In agreement, a separate study documented that LPS/IFN-γ-activated macrophages also experience a shift from respiration to fermentation, however succinate efflux was not measured (66). In the present study, M3+ macrophage cells showed elevated succinate efflux (Figure 9) in addition to the previously discussed diminishment in respiration (Figures 5A and 8A). Altogether, the present study and previous studies (65) (66) indicate that activated macrophage cells experience a diminished respiration as well as an elevated succinate efflux. Therefore, elevated succinate efflux is either a direct response to macrophage activation or a direct response to a diminished respiration. Tumor cells with a TCA cycle respiratory defects also elevate succinate efflux (76). Further, succinate levels elevate in oxygen deprived diving animals, oxygen-deprived rabbit heart, and oxygen-deprived tumor cells (77) (78) (79). Thus, elevated succinate seems to be more of a response to a diminished respiration than to the activated state of macrophages. A likely scenario is that macrophage activation in-vitro leads to a diminished respiration and a diminished respiration leads to elevated succinate efflux. Therefore, succinic acid is emerging as a candidate metabolic marker for a diminished respiration and a diminished respiration seems to be a response of activated macrophages in-vitro.

Arginine is also an important metabolite in macrophage cells, *M. arginini* metabolism, and the cancerous state (19) (80) (81) (82). In the present study,
metabolomic analysis showed an arginine to citrulline metabolism in the M3+ cells. Arginine to citrulline metabolism indicates the production of Nitric Oxide (NO). NO is a sign of macrophage activation and is made by inducible Nitric Oxide Synthase (iNOS), an enzyme that metabolizes O2, NADPH and arginine to water, citrulline and NO. Since NO is difficult to measure and because no other enzyme is known to metabolize arginine to citrulline in mammalian cells, NOS activity and NO can be conveniently assessed by measuring conversion of radio-labeled arginine to citrulline (67). I speculate that the M3+ cells are producing NO on the basis of a drop in arginine levels compared to the M3- cells coupled with citrulline production, which is absent in the M3- cells (Figure 10). On the other hand the arginine to citrulline metabolism in the M3+ cells may stem from the metabolism of *M. arginini* itself. Arginine deiminase from arginine-utilizing mycoplasma like *M. arginini* also metabolizes arginine to citrulline. As a result arginine deiminase has been found to be masquerading as nitric oxide synthase in mycoplasma infected cultures (8). Thus it is unclear whether the arginine to citrulline metabolism measured in M3+ cells indicates activation-induced NO production or whether it is simply a product *M. arginini* arginine deiminase metabolism. Activation-induced NO production is the more likely scenario explaining arginine to citrulline metabolism since M3+ cells also showed elevation of activation-associated itaconic acid and succinate production. In agreement with the concept that arginine to citrulline metabolism results in NO production in M3+ cells, the presence of *M. arginini* is sufficient to cause NO and TNF-α production in macrophage cells (70) (83).
Elevated proliferation associated with *M. arginini* infection is dependent on high cellular density

The enhanced proliferation in M3+ cells is concomitant with an increase in the macrophage activation-metabolites itaconic acid, succinate acid, and citrulline. However, M3+ cells show no increase in proliferation in low-density culture suggesting that M3+ cells may not be activated at low cellular density. Therefore, *M. arginini* only exerted its mitogenic effects at high cellular density. The increased proliferation of M3+ cells over M3- cells at high cell density could be a result of an activation product that concentrates in the culture media. For example, mycoplasmas have been shown to induce macrophages to secrete granulocyte-monocyte colony stimulating factors (GM-CSFs) (5), which may accrue in the cell culture media to cause proliferation during high-density M3+ cell culture. Further studies with the M3+ cells in low and high density will be needed to uncover the mechanism behind the increase of high-density proliferation of the M3+ cells over that of the M3- cells.

**Crabtree effect-induced suppressed respiration is separate from *M. arginini*-induced diminished respiration**

All cancer cells are known to experience a Crabtree effect and there is no mention in the literature of cancer cells that fail to do so (84) (85) (86). Normal non-transformed, non-tumorigenic cells do not experience a Crabtree effect (58) (59). Some activated immune cells experience a Crabtree effect (60), but it is unclear
whether these Crabtree positive immune cells would persist to experience a Crabtree effect in the non-activated state. The Crabtree effect seems to be derived from a over-sensitive hyperactive glycolytic system that siphons the ADP pool away from respiration and thus suppresses respiration \((59) (87)\), however it is unknown how this deregulation of glycolysis is initiated. Therefore the lactate produced during the Crabtree effect is not due to an increased glycolysis but rather from the suppressed respiration system. Since glucose is always present in-vivo and in-vitro, cancer cells experience a constant diminished respiration due to the suppressive effects of the Crabtree effect. In agreement, our study shows that both tumorigenic M3+ cells and M3- cells experience a Crabtree effect (Figure 8A). It is unclear why M3+ cells have a smaller % Crabtree effect than the M3- cells (Table 1), however a reduced Crabtree effect like seen in the M3+ cells has been associated with uncoupling of respiration with phosphorylation of ADP \((59)\). Thus in concordance with their tumorigenicity and as a result of the ubiquitous nature of glucose, both \(M. \ arginini\)-infected M3+ cells and eradicated M3- cells experience a glucose-induced constitutive diminished respiration due to the Crabtree effect.

In addition to the diminished respiration caused by the Crabtree effect, the infected M3+ cells experience another separate reduction in respiration compared to the M3- cells (Figure 5A & 7). Presumably the separate reduction in respiration is due to the presence of \(M. \ arginini\). The \(M. \ arginini\)-associated reduction in respiration of the M3+ cells is separate from the reduction caused by the Crabtree effect. As a result the \(M. \ arginini\)-associated reduction in respiration is seen in the Crabtree
positive condition (+glucose) and also when the Crabtree effect is circumvented (-glucose). When the Crabtree effect is circumvented in both M3+ and M3- cells, the M. arginini-associated reduction in respiration is exacerbated (Figure 7: Compare M3+ and M3- minus glucose condition). Thus, the M3+ cells exhibit two insults to respiration, one being the Crabtree effect and the other being the “M. arginini effect” per se.

**Diminished respiration is concomitant with enhanced fermentation in VM-M3 cells infected with M. arginini**

Respiration and fermentation negatively regulate each other and therefore are intrinsically linked. For example, during the Crabtree effect glucose induces an over-active fermentation and as a result the respiration system is suppressed (59). In agreement, hypoxia and respiratory inhibitors halt respiration and fermentation is up-regulated to energetically compensate for lost respiration. However, the reduced respiration of M3+ cells compared to M3- cells is not accompanied by an increase in fermentation after correction of the fermentation rate (lactate production) to the milligrams of protein (Figure 5C). Similarly, the M3+ cells would be expected to increase lactate fermentation rate to the same extent as the M3- cells when challenged with the respiratory inhibitor Antimycin A, but M3+ cells produce significantly less lactate than the M3- cells (Figure 5C + Ant A condition). The possibility exists that M.arginini is respiring the lactate produced by M3+ cells and thus an increase in fermentation rate would be masked. Respirometry studies have shown that both fermentative and non-fermentative mycoplasmas can respire
lactate and various other metabolic fuels for energy. *M. hominis*, a non-fermentative mycoplasma similar to *M. arginini*, is able to respire butyryl-CoA, succinate, NADH, NADPH and lactate (88) (89). The fermentative *M. gallisepticum* can also respire lactate and various other mycoplasma species have been shown to respire ethanol, glucose, acetate, and short chain fatty acids (90). Therefore, *M. arginini* could possibly be respiring the lactate produced by M3+ giving the false impression that fermentation rate is not increasing. The possibility that *M. arginini* is interfering with lactate measurements in this study is in agreement with previous reports on mycoplasma falsifying many metabolic and non-metabolic cellular assays (8) (9) (10).

Another more substantiated reason that *M. arginini* could be interfering with lactate measurements is the fact that lactate production was corrected to the milligram protein and that the protein content of M3+ cells could be overestimated due to the addition of *M. arginine*-derived protein. For example, if *M. arginini* protein amounted to 10% of the total M3+ protein quantified then the actual M3+ protein would be incorrectly overestimated. An overestimation of M3+ protein results in an underestimation of the fermentation rate (nmoles lactate / hr / mg protein value used in Figure 5C). In support of this notion, the extracellular lactate concentration measured by mass spectrometry was greater for M3+ cells compared to M3- cells since the mass spectrometry data was corrected to cell number rather than to milligram protein (Figure 18A). Additional evidence that M3+ cells increase fermentation in response to diminished respiration is derived from studies done
with M3II cells, a different clone than M3 but derived from the same initial VM-M3 tumor. Enzymatic lactate measurements were greater in M3II+ cells than M3II- cells when corrected to ATP levels (Figure 18B), suggesting that a decrease in respiration occurred in conjunction with an increase in fermentation. Ultimately, cellular assays done with mycoplasma-infected cell cultures need to be corrected by multiple parameters unless mycoplasma protein amount can be accurately separated from cellular protein amount in the assay being performed. Nonetheless, the possibility exists that in the present study *M. arginini* is interfering with lactate production when corrected to the milligram of cellular protein.

**Possible mechanism of *M. Arginini*-induced diminished respiration.**

The mechanism behind the decline in respiration by the *M. arginini* effect on M3+ cells is unknown. It seems clear that the diminished respiration by the *M. arginini* effect involves activation of M3 macrophage cells since *M. arginini* is capable of activating macrophages (70). Both *M. arginini*-activated and LPS-activated macrophages have been shown to release NO (70) (71) and other mycoplasma species can also induce NO release in macrophage cells (91). NO is a powerful respiratory inhibitor (92). Activated macrophages have been shown to severely diminish the respiration of six different cancer cell lines during co-culture, however the implications of NO were not discussed (93). In addition, activated macrophages are capable of injuring neurons partly through NO production, possibly diminishing neuronal respiration (71). Therefore activated macrophage metabolism in-vitro is sufficient to diminish the respiration system of co-cultured cells, partly do to NO
production. If activated macrophages can diminish the respiration of co-cultured cells then it should be possible that they are at the same time diminishing their own respiration in-vitro. Thus, perhaps the diminished respiration in M3+ cells is in part self-promoted by activation-induced NO production. If this scenario were true, it would mean that *M. arginini* activates M3+ cells and as a result M3+ cells produce NO that diminishes their own respiration as well as the respiration of neighboring M3+ cells. It has indeed been shown that activated macrophages experience a diminished respiration in-vitro (65) (66), but it is unclear whether the diminished respiration is a natural part of macrophage activation-induced catabolism or is rather an effect from an inflammatory secreted molecules such as NO or TNF-α (TNF-α also disrupts respiratory energy production (94)).

**Potential mechanism of *M. arginini*-induced tumor progression**

As mentioned above, the present study suggests that the presence of *M. arginini* leads to activation of M3 cells, a concomitant inflammatory response, and a diminished respiration. As tumor-promoting inflammation is an enabling characteristic of the hallmarks of cancer and deregulation of cellular energetics is an emerging hallmark of cancer, NO and TNF-α production by M3+ cells is perhaps leading to their diminished respiration. *M. arginini* induced inflammation in vivo is partly a probable cause of the tumor progression increase seen when inoculating M3+ cells in-vivo compared to M3- cells.
**Therapeutic Implications**

Mycoplasmas can be detected in a high percentage of a wide variety of primary human cancers (42) (43) (44) (45). Some mycoplasma species can cause cells in culture to be tumorigenic but studies injecting these species into animals and assessing any cancer causing potential or cancer promoting potential are lacking. However, mycoplasmas enable many of the hallmarks of cancer (5) (31) (32) (24) (33) (34) (35) (37) (38) (39) (40), and thus mycoplasma-targeted therapies could offer relief from progression and thus more time to patients with mycoplasma-infected cancers. For example, 55% of glioblastoma specimens (out of 35) tested positive for cytomegalovirus (95) and when antivirals against cytomegalovirus were given to glioblastoma patients, survival significantly improved (96). Interestingly, cytomegalovirus induces bio-energetic changes reminiscent of *M. arginini* infection in M3 cells (97) (98) (99). The present study warrants further investigation into the role mycoplasmas play in human cancer and to the extent in which mycoplasma infections present in human cancer. If mycoplasmas are found to play a major causative or provocative role in human cancer in a variety of cancers, mycoplasma-targeted therapies could prove efficacious in prevention of cancer and prolonging mycoplasma-infected patient survival.
Figure 1. Eradication of Mycoplasma Infection in VM-M3 cells. (A) A 1.5% agarose gel with amplified DNA products which include a positive control (+cont), the infected M3 cells (M3+), the eradicated M3 cells (M3—) and the negative control (cell growth media). The top band at 570 bp is an amplified Human / Mammalian-specific DNA sequence controlling for the presence of human or mammalian cells. The 260 bp band is the amplified extracted 16S rDNA gene capable of identifying 182 Mycoplasma species. The lower faint band is an amplified internal control band of an artificial gene derived from the human TNFα gene. MycoZap (Lonza) and a subsequent treatment with ciprofloxacin were used to eradicate the infection (M3—). The positive control is amplified extracted DNA from Mycoplasma fermentans infected K562 cells. The negative control is fresh DMEM high glucose plus 10%FBS. (B) The eradication was stable for up to three weeks in culture without the use of prophylactic methods.

**Figure 3. Energy catabolism in mammalian cells.** Energy Catabolism in mammalian cells is comprised from respiration (oxidative phosphorylation) and lactate fermentation. Pyruvate, fatty acids, amino acids, and the malate-aspartate shuttle all provide NADH to power oxidative phosphorylation (OXPHOS). The glycerol-3-phosphate shuttle and succinate provide FADH2 to power OXPHOS. NADH and FADH2 transfer high-energy electrons to the electron transport chain (Complexes I through IV) in which oxygen is the final low energy electron acceptor. The energy harnessed from high-energy electron transfer by complexes I through IV is used to pump protons into the inter membrane space creating a proton gradient that flows back into the mitochondrial matrix while ATP is synthesized by complex V. Normal mammalian cells derive the major percentage of their energy through respiration with lactate fermentation rarely providing over 20% of energy needs. If energy through respiration is limited by hypoxia or pharmacological inhibition, lactate fermentation will increase in attempts to compensate for the lost respiratory energy. It is unclear if and in what cell types fermentation energy can completely replace the loss of all respiratory energy. Respiration is classically measured by oxygen consumption and lactate fermentation through lactate production. Accepted values are 5 moles of ATP produced for every mole of oxygen consumed and 1 mole of ATP for every mole of lactate produced.
Figure 3
**Figure 4. Measurement of energy catabolism with a Seahorse XF-96 Flux Analyzer.** (A) A picture of the Seahorse XF-96 Flux Analyzer unit is shown with a 96-well plate loaded in the retractable slot on the right. The Seahorse XF-96 used in the studies within this thesis resides at Berg Pharma. (B) A cartoon side-view of two individual wells of a Seahorse XF96 specific 96-well plate. To the left of the boxed number 1, cells (green spheres) can be seen on the bottom of the well. Boxed number 2 represents the oxygen (orange) and pH (blue) measurement probes that rise up and dip down into the media (pink) of the incubating cells. Boxed number 3 shows drug-dispensing ports that can inject drugs of choice into the media at specified times. (C) During oxygen and pH measurements the probe travels down to create an air tight compartment right above the cells (7 ul of volume total). When the sensor probes are completely down a closed system is created in which oxygen rate can be assessed. To prevent hypoxic conditions, after a short measurement is complete (7 minutes in this study), the probe travels back up (as in B) to allow the oxygen, pH, and nutrients to re-equilibrate.
Figure 4
Figure 5. Comparison of oxygen consumption, ECAR, and lactate production of M3+ and M3— cells in the presence and absence of Antimycin A. Oxygen consumption rate (A) Extracellular acidification rate (ECAR) (B), and Lactate production rate (C) in M3+ and M3— cells. Complete media is DMEM with 2 mM glutamine, 10 mM glucose, and 0.5 mg/mL Albumax I. No FBS and no bicarbonate was included as recommended by Seahorse for ECAR measurements. Phenol red was not included since visual pH monitoring was unnecessary. The concentration of Antimycin A was 100 nM. Oxygen consumption, ECAR, enzymatic lactate, and protein were all measured from the same well using a Seahorse XF96 Analyzer. In the —Antymycin A condition n=8 and in the + Antymycin A condition n=4. Error bars represent 95% confidence intervals calculated using Excel. * = p < 0.05 ** = p < 0.01 (determined by the two tailed student t-test).

**Introduction**

Mycoplasmas of the Mollicutes class are considered the smallest self-replicating free-living prokaryotes (1). Mycoplasma 16S rRNA sequencing data used as a phylogenetic measure suggests that mycoplasmas originated from walled gram-positive eubacteria by degenerative evolution roughly 600 million years ago (2). Unlike their walled ancestors, the Mollicutes (soft skin) class lacks a cell wall and thus is resistant to common bacterial cell wall targeted antibiotics such as penicillin. Mycoplasmas range in size from 0.3µm to 0.8µm, which in turn reflects their small genome sizes. *M. genitalium* has the smallest genome (580 kb) of any organism that can be grown in pure culture and *M. hyorhinis* has the largest genome of the mycoplasmas (820 kb) (3) (2) (4). With limited coding capacity, the mycoplasma genus has stringent nutritional requirements for fatty acids, sterols, some amino acids, nucleic acids, and various vitamins/cofactors (4) (5). Dependence on metabolic precursors for life leads to the need of extremely complex media in order to cultivate and therefore study mycoplasmas. However, high mycoplasma infection rates show that mycoplasmas propagate well within or attached to mammalian cells in-vitro (6) (1).

Mycoplasma infection of cultured mammalian cells can falsify many metabolic and non-metabolic cellular assays including oxygen consumption assays (7), nitric oxide synthase activity (8), MTT viability assays (9), and mitochondrial protein synthesis determination (mycoplasma co-purified with the mitochondrial fraction) (10). In agreement, *M. hominis* infection of HeLa cells significantly altered genetic expression
profiles of 1972 genes (11). Another study found approximately 200 significant expression profile alterations in infected MCF7 cells and 70 of those genes were involved in metabolism (12). In Mycoplasma pneumoniae-infected individuals, tracheal cell explants were shown to have a decrease in ATP from respiration, possibly due to lower dehydrogenase activities of the cells (10). Similarly, M. hyorhinis is also capable of reducing the respiration system in heavily contaminated human skin fibroblast cells (13). Thus, mycoplasmas have a high potential for modulating host metabolism.

Regarding energy catabolism, mycoplasmas can be classified as fermentative or non-fermentative (14). Fermentative mycoplasmas are able to gain energy by substrate-level phosphorylation of ADP by glycolysis, specifically by the Embden-Meyerhof-Parnas (EMP) Pathway (14). Fermentation produces acid and occurs not to specifically make energy, but rather to oxidize NADH to allow glycolysis to continue to make energy (NAD+ is required for the 6th step of glycolysis) (15). Therefore, fermentative mycoplasmas are acidifiers and thus reducers of their environment. Some fermentative mycoplasmas such as M. gallisepticum have the ability to carry out a non-fermentative catabolism (16) (17) but viability and growth during a non-fermentative catabolism are unclear. However in the presence of glucose, fermentative mycoplasmas produce a net waste of acid. In contrast, non-fermentative mycoplasmas do not produce a net waste of acid or alcohol, which indicates that their energy catabolism is mainly oxidative. In part, the oxidative catabolism of the non-fermentative mycoplasmas is perhaps due to the lack of
